**Helicobacter pylori** Prevalence and Circulating Micronutrient Levels in a Low-Income United States Population

Meira Epplein1, Lisa B. Signorello1,4, Wei Zheng1, Qiuyin Cai1, Margaret K. Hargreaves3, Angelika Michel5, Michael Pawlita5, Jay H. Fowke1, Pelayo Correa2, and William J. Blot1,4

**Abstract**

High prevalence of *Helicobacter pylori* (*H. pylori*), the leading cause of gastric cancer, and low levels of micronutrients have been observed in many developing countries, and the question remains as to whether an association between the 2 exists. The present study seeks to further our understanding of this potential connection in the Southern Community Cohort Study, representing a low-income population in the United States. Blood levels of antibodies to *H. pylori* proteins were assessed by multiplex serology for a sample of 310 African American and white participants, ages 40 to 79 years. Blood collected at baseline was also assayed for levels of carotenoids, tocopherols, retinol, and folate. Multivariate linear regression was used to calculate least-squares mean micronutrient levels within groups defined by *H. pylori* status. The mean serum levels of all micronutrients assayed were lower among *H. pylori*+ individuals than *H. pylori*– individuals, significantly for β-carotene, folate, and retinol (decreases of 27.6%, 18.6%, and 9.7%, respectively). Individuals who were seropositive to the virulent CagA+ *H. pylori* strains had even lower mean levels of micronutrients, particularly β-carotene, folate, total carotenoids, and retinol (decreases of 38.9%, 19.1%, 17.0%, and 11.7%, respectively, compared with *H. pylori*– individuals). However, dietary micronutrient levels as derived from a food frequency questionnaire did not vary between groups defined by *H. pylori* status. These results provide support for the hypothesis that *H. pylori* infection impairs nutrient absorption and suggest a need for future studies to explore the role of *H. pylori* infection on nutrition and gastric cancer risk in this high-risk population. Cancer Prev Res; 4(6); 871–8. ©2011 AACR.

**Introduction**

Infection with *Helicobacter pylori* (*H. pylori*), a gram-negative spiral bacterium that induces chronic gastritis in half of the world’s population, is the leading cause of gastric cancer (1), the second most deadly cancer worldwide (2). Within both high- and low-risk countries, gastric cancer incidence, like *H. pylori* prevalence, is also strongly associated with low socioeconomic status (3). Recently, a study of trends in incidence of noncardia gastric cancer (the type most significantly associated with *H. pylori*) found that incidence was generally decreasing in the United States as expected, although age-specific analyses suggest that the decline may be beginning to end (4). In the United States, where gastric cancer is uncommon, there is still a large racial disparity, as African Americans have almost twice the likelihood of being diagnosed with gastric cancer as whites (5). Similarly, the overall *H. pylori* prevalence in the United States is estimated to be relatively low at around 30% (although 50%–60% for African Americans; ref. 6), but a surprising 80% of a biracial sample of Southern Community Cohort Study (SCCS) participants, a primarily low-income study population from the southeastern United States, were recently found to be seropositive for *H. pylori* (7).

Because of the generally consistent findings from observational studies that implicate diet in the etiology of gastric cancer, in 2007, an expert panel of the World Cancer Research Fund judged that there is probably an evidence that fruit intake protects against gastric cancer (8). However, although a number of randomized trials of vitamin supplementation (including nutrients such as β-carotene, ascorbic acid, folic acid, α-tocopherol, selenium, and zinc) have been conducted, only 2 of 7 studies have reported benefits in the prevention of gastric premalignancy and 2 of 9 studies have found significant protective effects for gastric cancer (9).

Another hypothesis for the association of nutrient levels and gastric cancer risk relates to the role of *H. pylori*. Instead of high nutrient levels protecting against *H. pylori* infection,
it has been suggested that infection with *H. pylori* itself reduces the absorption of nutrients (10, 11). This hypothesis is based on the fact that chronic *H. pylori* infection is generally begun in childhood, and thus nutrient levels measured among adolescents and adults are more likely to reflect *H. pylori* status, rather than the other way around. Furthermore, while nutrients are not absorbed in the stomach, *H. pylori* infection affects acid secretion that is vital for nutrient absorption. Several studies have found that the concentration of certain micronutrients found in plasma, gastric juice, and gastric mucosa is lower in *H. pylori*-infected subjects (12).

In this study, we examined the association between *H. pylori* prevalence and circulating levels of micronutrients in the SCCS, representing a low-income U.S. population with high prevalence of *H. pylori* infection.

**Materials and Methods**

**Study population**

From 2002 to 2009, the SCCS recruited approximately 86,000 men and women, ages 40 to 79, from 12 southeastern states (13). Those who enrolled in person at community health centers (approximately 86%) completed a comprehensive computer-assisted-in-person interview, providing information on demographics, anthropometrics, medical history, and cancer risk factors (questionnaire available at: http://www.southerncommunitystudy.org). A food frequency questionnaire (FFQ), validated in this population, was used to collect information on usual diet (14, 15). Those recruited by mail (approximately 14%) completed the same baseline survey, by paper. Race was self-reported with participants instructed to choose all applicable racial/ethnic categories. Venous blood samples (20 mL) were collected from participants at the time of their baseline interview at the community health center, then refrigerated and shipped overnight to Vanderbilt University, Nashville, TN, to be centrifuged the next day and stored at −80°C. By using a 2×2×3×3 factorial design with 22 individuals selected within each of the 36 strata defined by self-reported race (African American/white), sex, smoking status (current/former/never), and body mass index (BMI, 18–24.9/25–29.9/30–45 kg/m²), 792 of the 12,162 participants who enrolled in the study from March 2002 to October 2004 and donated a blood sample at baseline were randomly selected. While this design meant that some populations from within the entire SCCS were oversampled (including whites, nonsmokers, and nonobese participants), it provided a balanced distribution across these factors in consideration of other blood biomarkers being measured in addition to *H. pylori*.

**H. pylori multiplex serology**

For each study subject, 50 μL of serum samples were aliquoted for *H. pylori* assays. *H. pylori* multiplex serology, as performed in this study, has been described recently (16). In summary, it is a new antibody detection technology on the basis of fluorescent polystyrene beads (Luminex) and recombinant glutathione S-transferase fusion protein capture (17, 18). For all 15 antigens—the *H. pylori* proteins UreA, catalase, GroEL, NapA, CagA, CagM, CagB, HP0231, VacA, HpaA, Cad, HyuA, Omp, HcpC, and HP0305—previously determined antigen-specific cut-point values were applied by using a bridging panel of 78 previously characterized sera (which included 38 *H. pylori* negative sera and 40 *H. pylori* positive sera). All sera were analyzed once within a single assay day. Individuals with seropositivity to more than 3 proteins were considered to be *H. pylori* seropositive as this definition had shown good agreement with commercial serological assay classification.

**Blood nutrient measurement**

To study nutritional biomarkers, plasma or serum for exactly half (396) of the individuals selected by the sampling design mentioned before (11 from each of the 36 strata) was assayed for micronutrient levels. Details on the measurement of plasma α-carotene, β-carotene, β-cryptoxanthin, lutein plus zeaxanthin, lycopene, and α-tocopherol levels using assays based on high-performance liquid chromatography, and the analysis of serum folate levels using a microbiologic assay, have been recently published (15). Retinol was measured by the use of a second channel at a wavelength of 325 nm. Quality control procedures included routine analysis of plasma and serum control pools containing high and low concentrations of each analyte. The coefficients of variation were less than 10% for all analytes and control pools.

**Statistical analysis**

Of the 396 participants selected for the nutritional biomarker sample, 310 (78.3%) were included in this study. The available serum for *H. pylori* multiplex serology was depleted from other assays performed on this group for 77 (19.4%) samples for 3 (0.8%) individuals could not be assayed for *H. pylori* because of serum handling issues, 2 (0.6%) individuals tested seropositive for CagA but seronegative for *H. pylori* (as they were each seropositive to less than 4 *H. pylori* antigens total), and 4 (1.0%) individuals were missing data on the potential confounders of total daily energy intake and/or vitamin supplement use.

To assess differences in demographic and lifestyle characteristics between *H. pylori*+ and *H. pylori*− individuals, crude linear regression was used for the continuous variables of age and daily energy intake and the Mantel–Haenszel chi-square test was used for the remaining categorical variables. To determine the associations between the prevalence of *H. pylori* infection and blood nutrient levels, multivariate linear regression was used to calculate least-squares mean micronutrient levels within groups defined by *H. pylori* status in 2 ways: as a dichotomous variable (*H. pylori*− versus *H. pylori*+), and as dummy variables, comparing *H. pylori* seronegative individuals to those seropositive to *H. pylori* but not to CagA (*H. pylori*+, CagA−), and those seropositive to both *H. pylori* and CagA (*H. pylori*+, CagA+), and comparing mean micronutrient...
levels between CagA seropositive and CagA seronegative individuals among those who are *H. pylori* seropositive. Multivariate linear regression models were also carried out to explore the association of micronutrient levels with seropositivity to each of the 15 individual *H. pylori* antigens assessed with multiplex serology. For the outcome of circulating levels of each micronutrient, blood nutrient levels were log-transformed as they were not normally distributed. A category of total carotenoids was created by summing the log-transformed values for α-carotene, β-carotene, lycopene, lutein and zeaxanthin, and β-cryptoxanthin. Statistical adjustment was made for age at enrollment (continuous), race (African American/white), sex, BMI (continuous), education (less than high school education/high school or GED/greater than high school education), smoking status (never/former/current of less than or 10 cigarettes per day/current of more than 10 cigarettes per day), regular (i.e., ≥ once a month) use of vitamin supplements (primarily multivitamins) in the last year (yes/no), and total energy intake (continuous). Additional adjustment for income, fruit and vegetable intake, dietary fat intake, alcoholic drink consumption, health insurance status, family history of gastric cancer, and state where recruited was considered, but these variables were not associated with both the exposure and outcome in the data, and thus were not included in the final models. To evaluate potential effect modification, the association of *H. pylori* infection and serum nutrient levels was explored in separate models stratified by race, sex, and smoking status, and a likelihood ratio test was used to compare models with and without the respective interaction terms.

To examine the association of *H. pylori* status and dietary intake of micronutrients, secondary analyses were done by micronutrients levels of intake as derived from the FFQ, also log-transformed due to a skewed distribution. Multivariate linear regression was again used to calculate least-squares mean dietary micronutrient levels within groups defined by *H. pylori* status, as described before.

In the results presented in this article, the mean levels of micronutrients have been backtransformed so to be scientifically meaningful. The percentage difference in levels as shown in the tables, however, reflects the difference between the log-transformed values, and thus is slightly different from what one would calculate by using the backtransformed values presented.

All statistical analyses were done by SAS 9.2 (SAS Institute).

**Results**

Of the 310 individuals included in this study, 244 (79%) were seropositive for *H. pylori*. *H. pylori* seropositive individuals were more likely to be African American, have less than a high school education, and a first-degree family history of stomach cancer than *H. pylori* seronegative individuals (Table 1).

For the combined category of total carotenoids and all individual micronutrients, the mean circulating level as derived from serum assays was higher among *H. pylori*—individuals than *H. pylori*—individuals. The differences in mean levels for *H. pylori*—individuals, compared with *H. pylori*—individuals, were statistically significant for β-carotene, folate, and retinol (decreases of 27.6%, 18.6%, and 9.7%, respectively; Table 2).

When examining the associations between circulating nutrient levels and *H. pylori* prevalence by CagA status with 1 exception (lutein and zeaxanthin), *H. pylori*—individuals had the highest mean levels of all micronutrients with lower levels for *H. pylori*—individuals, and the lowest levels among *H. pylori*—individuals. By comparing *H. pylori*—individuals with *H. pylori*—individuals, statistical significance for the difference in mean levels was achieved only for folate (an 18.1% difference). For *H. pylori*—individuals, CagA+ individuals, however, significant differences in mean levels compared with *H. pylori*—individuals were found with β-carotene, folate, total carotenoids, and retinol (decreases of 38.9%, 19.1%, 17.0%, and 11.7%, respectively). Furthermore, *H. pylori*—, CagA+ individuals had significantly lower levels of β-carotene, lycopene, and total carotenoids than *H. pylori*—, CagA+ individuals (decreases of 26.4%, 15.6%, and 13.4%, respectively; Table 3). By including *H. pylori* seroprevalence by CagA status, the $r^2$ value of the model for our strongest association, with β-carotene, increased from 0.23 to 0.27 for the model without any information on *H. pylori*, a small increase despite the strong and significant effect of *H. pylori* status found in the model.

Of the other *H. pylori* antigens explored, only seropositivity to VacA also seemed to be associated with micronutrient levels. However, VacA is strongly correlated with CagA (Pearson correlation coefficient $= 0.38$, $P < 0.0001$), and after adjusting for CagA seropositivity, the associations with VacA seropositivity were no longer present.

When stratifying by smoking status (current versus never/former), *H. pylori*—smokers had lower levels of almost all carotenoids than *H. pylori*—nonsmokers, and there was a consistent trend of a greater percent decrease in blood carotenoid levels among the *H. pylori*—, CagA+ current smokers than among the *H. pylori*—, CagA+ non-current smokers, when comparing to *H. pylori*—individuals within the same smoking category, but the differences were not statistically significant (see Appendix Table 1). The associations between *H. pylori* status and circulating nutrient levels did not vary when examining the relationships separately by sex or race (data not shown).

To further explore the association between *H. pylori* status and micronutrient levels, we ran the same models using as the outcome micronutrient intake as determined by the FFQ, rather than the blood levels as used previously. While *H. pylori*—individuals tended to have lower mean intakes than *H. pylori*—individuals, the differences were neither large nor significant, and there was no trend of decreasing levels as before when moving from the categories of *H. pylori*—to *H. pylori*—, CagA— to *H. pylori*—, CagA+ (Table 4).
In this low-income highly *H. pylori*-prevalent population in the southeastern United States, *H. pylori* prevalence, particularly CagA+ *H. pylori* strains, was associated with lower blood levels of β-carotene, folate, and retinol.

The few previous studies of the association between *H. pylori* infection and plasma carotenoid and folate levels...
have generally found null results (19–22). Compared with the present study, these small (ranging from 44 to 86 individuals) clinic-based studies had less power and could not investigate specific *H. pylori* proteins. Inverse associations have, however, been observed between *H. pylori* infection and levels of β-carotene in gastric juice (20).

The strong associations between *H. pylori* status and blood nutrient levels observed in this study are made more interesting by the fact that the dietary intake of these micronutrients as determined by an FFQ was not associated with *H. pylori* status, lending support for the theory that *H. pylori* infection impairs the absorption of nutrients. Our data suggest that *H. pylori* seronegative and seropositive individuals have similar diets with regard to nutritional content, but their circulating levels of certain micronutrients are significantly different, most strongly for vitamin C and folate. This is in contrast to the findings of associations between *H. pylori* seroprevalence and low levels of circulating micronutrients observed in Linxian (6.4 mcg/dL; ref. 26), where intervention trials showed reduced gastric cancer incidence following nutrient supplementation with a combination of β-carotene, selenium, and vitamin E. SCCS β-carotene levels were significantly lower than those found at baseline in the European Prospective Investigation into Cancer and Nutrition (median, 19.0 mcg/dL; ref. 26), and in a Colombian vitamin supplementation trial (baseline presupplementation median, 23.9 mcg/dL; ref. 29). Our findings suggest that beyond supplement intervention trials, there are opportunities for both improving nutritional status and reducing gastric cancer incidence in high-risk populations by directly dealing with the potential underlying cause—that of *H. pylori* infection. Methods to eliminate endemic *H. pylori* infection could include vaccine development and eradication schemes that are aided by vitamin supplementation.

The low-income population represented by the SCCS thus seems to have low circulating levels of antioxidants, particularly β-carotene, and a high prevalence of *H. pylori* infection, especially the virulent CagA+ *H. pylori* strains.

and our data suggest that this association may be due to the ability of \textit{H. pylori} to impair the absorption of nutrients. The presence of this combination of risk factors for gastric cancer also suggests that this population is a high-risk group, with a need for future studies to further explore the role of \textit{H. pylori} infection on nutrition and gastric cancer risk as the cohort is followed in the coming years.
