Eleostearic Acid Inhibits Breast Cancer Proliferation by Means of an Oxidation-Dependent Mechanism

Michael E. Grossmann, Nancy K. Mizuno, Michelle L. Dammen, Todd Schuster, Amitabha Ray and Margot P. Cleary

Abstract

Eleostearic acid (α-ESA) is a conjugated linolenic acid that makes up ~60% of Momordica charantia (bitter melon) seed oil. Prior work found that water extract from bitter melon was able to inhibit breast cancer. Here, we investigated effects of α-ESA on both estrogen receptor (ER)–negative MDA-MB-231 (MDA-wt) and ER-positive MDA-ERα7 human breast cancer cells. We found that α-ESA inhibited proliferation of both MDA-wt and MDA-ERα7 cells, whereas conjugated linoleic acid had comparatively weak antiproliferative activity at 20 to 80 μmol/L concentrations. We also found that α-ESA (40 μmol/L) treatment led to apoptosis in the range of 70% to 90% for both cell lines, whereas conjugated linoleic acid (40 μmol/L) resulted in only 5% to 10% apoptosis, similar to results for control untreated cells. Addition of α-ESA also caused loss of mitochondrial membrane potential and translocation of apoptosis-inducing factor as well as endonuclease G from the mitochondria to the nucleus. Additionally, α-ESA caused a G₂-M block in the cell cycle. We also investigated the potential for lipid peroxidation to play a role in the inhibitory action of α-ESA. We found that when the breast cancer cells were treated with α-ESA in the presence of the antioxidant α-tocotrienol (20 μmol/L), the growth inhibition and apoptosis effects of α-ESA were lost. An AMP-activated protein kinase inhibitor (Dorsomorphin) was also able to partially abrogate the effects of α-ESA, whereas a caspase inhibitor (BOC-D-FMK) did not. These results illustrate that α-ESA can block breast cancer cell proliferation and induce apoptosis through a mechanism that may be oxidation dependent.

A number of studies indicate that total dietary fat intake may play a major role in the development and progression of breast cancer in humans (1, 2). However, the impact of different types of fat in the diet on breast cancer development has proven complex with results from previous studies supporting both positive and negative roles for specific fats. Some long chain polyunsaturated fatty acids (LC-PUFA) have been reported to have protective effects as shown by an inverse relationship between high fish consumption and breast cancer first noted over 30 years ago (3, 4).

We have identified bitter melon as a plant containing a LC-PUFA that seems to have potential anticancer properties. Bitter melon originated in tropical Asia, but due to its apparent health benefits, it is now grown and used medicinally in many countries and is widely available in a variety of different supplement forms. Prior work showed that multiple types of extracts from bitter melon had in vivo (5–7) and in vitro (8) anticancer activity. Of particular interest to us is eleostearic acid (α-ESA), also known as 9Z,11E,13E-octadecatrienoic acid, a LC-PUFA that makes up ~60% of bitter melon seed oil. In vitro studies using pure α-ESA have reported antiproliferative activity. For example α-ESA significantly reduced viability of transformed NIH-3T3 mouse fibroblast (SV-T2) and monocytic leukemia (U-937) cells (9). In additional reports, DLD-1 colorectal adenocarcinoma cells treated with α-ESA in vitro were growth inhibited and underwent DNA laddering indicative of apoptosis (10), and both Caco-2 and HT-29 colon cancer cells had decreased viability and increased DNA fragmentation when treated with α-ESA (11). In a follow-up study using Caco-2 cells, α-ESA was again found to reduce cell viability and increase DNA fragmentation such as would be seen with apoptosis. Cell viability was maintained by addition of the antioxidant α-tocopherol in a concentration-dependent manner, suggesting that the reduction in viability is dependent on lipid peroxidation (12). The potential for α-ESA to inhibit breast cancer and possible mechanisms of action of α-ESA in breast cancer has not been addressed to this point.

In this study, we investigated the anticancer effects of purified α-ESA using human breast cancer cell lines with and without estrogen receptor by comparison of cell proliferation and apoptosis in the presence and absence of α-ESA. We have also
examined several potential pathways and mechanisms of action by which α-ESA may be functioning. Clarification of the actions of α-ESA may lead to a better understanding of how dietary fats impact cancer cells and to an improved ability to standardize an active ingredient of bitter melon extracts.

Materials and Methods

Cell culture
MDA-MB-231 cells were obtained from American Type Culture Collection and maintained in L-15 media (American Type Culture Collection) with 10% FCS (Atlanta Biologics) and pen/strep (Life Technologies). The MDA-ERα7 cell line (13) is a clone of the MDA-MB-231 cell line that has been transfected with the ERα gene followed by selection with 200 μg/mL of zeocin (Promega). The MDA-ERα7 cell line was maintained in 200 μg/mL zeocin-supplemented media.

Growth assays
Cells were harvested, counted, plated at a density of 5 × 10³ cells per well in 96-well plates, and allowed to attach overnight in an incubator maintained at 37°C without additional CO2. The following day, complete medium was removed from the wells and treatment of the cells with α-ESA in complete media was then done. When cells were treated with α-tocotrienol, it was given at the same time as the α-ESA. The cells were then incubated for 48 h, at which time a cell proliferation assay was done. The proliferation assay was done using 10 μL of CCK-8 reagent from the Cell Counting kit-8 as per manufacturer's instructions (Dojindo Laboratories). In this assay, a formazan dye is generated by the activity of dehydrogenases in cells that is directly proportional to the number of living cells. The plates were then incubated for 1.5 to 3 h depending on the cell line in a 37°C incubator, after which the plates were read and analyzed by fluorescence-activated cell sorting.

Western blots and immunofluorescence
For the Western blotting experiments, cells were plated at 5 × 10⁵ in six-well plates. The following day, the media was replaced with α-ESA for various times as described for each experiment. Whole-cell extracts were obtained as per the manufacturer's instructions for Novagen Phosphosafe extraction reagent (Merck KGaA) and the amount of protein quantitated and standardized. Western analyses were done with actin, poly ADP ribose polymerase (PARP), and rabbit secondary antibody from Cell Signaling Tech., and α-ESA and α-tocotrienol were obtained from Cayman Chemical. Western blots and immunofluorescence

Statistics
All data analysis was done using GraphPad Prism version 4.0. Proliferation assays were done three to eight times using triplicate wells each time and are presented as means ± SEMs. Two-way ANOVA was used to compare the data from the proliferation assays, and one-way ANOVA was used for the remaining studies with significant differences defined as at least a P value of <0.05. If the one-way ANOVA was significant, then the Newman-Keuls postest was used to compare all pairs of columns. Significance between specific groups using Newman-Keuls was defined as at least a P value of <0.05.

Results

Ability of α-ESA to inhibit breast cancer growth and induce apoptosis
We assessed whether α-ESA possesses anticancer activity against breast cancer using estrogen receptor (ER)–negative MDA-wt and ERα-positive MDA-ERα7 cells. Our initial doses of α-ESA were dictated by prior work with other cell lines (9–11). Here, we found that α-ESA inhibited proliferation of both breast cancer cell lines at 20 μmol/L (P < 0.05), 40 μmol/L (P < 0.001), and 80 μmol/L (P < 0.001), whereas CLA and ALA, though very similar to α-ESA structurally, had comparatively weak antiproliferative activity at these concentrations (Fig. 1A). Prior work with MDA-MB-231 cells with CLA at higher doses found there was a significant reduction in proliferation (14); however, another study using a variety of cell lines (DLD-1, Hep G2, A549, MCF-7, and MKN-7) reported that at the lower concentrations such as what we used, there was negligible inhibition of proliferation (15).

goal for treatment of breast cancer, so we examined apoptosis using a fluorescence-activated cell sorting–based Annexin V assay. To do this, we treated the cells for 48 hours with 40 μmol/L α-ESA because this dose gave us an effect of ~80% inhibition of cell proliferation. We found that α-ESA treatment resulted in a high level of apoptosis for both cell lines, 82% and 89% for the MDA-ERα7 and MDA-wt cells, respectively (P < 0.0001) compared with their respective untreated control cells. CLA and ALA treatment resulted in only 5% to 10% of cells in apoptosis, which was similar to results for control cells (Fig. 1B). These results clearly illustrate that α-ESA has very profound direct anti-breast cancer effects in vitro.

Ability of antioxidants to block α-ESA effects

To determine potential mechanisms of action for α-ESA, we investigated the potential for lipid peroxidation to play a role in the antiproliferative affect that α-ESA exerted on the breast cancer cells. To do this, we treated the cells with α-tocotrienol, a form of vitamin E that has antioxidant activity (16). We hypothesized that the use of an antioxidant should reduce reactive oxygen and nitrogen species and lipid peroxidation that would in turn prevent inhibition of breast cancer by α-ESA. Figure 2A shows that when the cells were treated with α-ESA in the presence of 20 μmol/L α-tocotrienol, growth inhibition by α-ESA was attenuated with the cells retaining 70% and 72% of their proliferation potential for the MDA-ERα7 and MDA-wt cells, respectively, at the α-ESA concentration of 80 μmol/L. The differences were statistically significant at 20 μmol/L (P < 0.01), 40 μmol/L (P < 0.001), and 80 μmol/L (P < 0.001). To further characterize the dependence of α-ESA actions on an oxidation-dependent mechanism, we measured apoptosis in the presence or absence of 20 μmol/L α-tocotrienol. Treatment with 20 μmol/L α-tocotrienol alone did not alter...
Fig. 3. α-ESA treatment effects on the mitochondrial membrane potential and translocation of AIF and endoG. One-way ANOVA $P < 0.0001$ for the difference between the treatments as a whole. A, cells were treated with α-ESA in the presence or absence of 20 μmol/L α-tocotrienol (Toc) for 48 h. Y-axis, cells with disruption of the mitochondrial membrane in percent. The concentration of α-ESA was 40 μmol/L and the concentration of α-tocotrienol was 20 μmol/L. B, MDA-ERα7 cells and C) MDA-wt cells were treated with 40 μmol/L α-ESA for the times shown above each panel. Untreated cells were given complete media. Green, positive staining for AIF and ENDOG; blue, positive staining for 4′,6-diamidino-2-phenylindole (DAPI) staining of DNA. The cells were observed and photographed with an oil lens at ×630 magnification.
apoptosis levels compared with untreated controls. In addition, the ability of α-ESA to induce apoptosis was blocked by α-tocotrienol (Fig. 2B), leading to levels of apoptosis similar to that of untreated controls.

**The intrinsic apoptosis pathway and α-ESA.**

To identify what parts of the apoptosis pathway are important for the effects of α-ESA, we determined whether the Δψm was affected by α-ESA treatment. Cells were incubated with 40 μmol/L α-ESA for 48 h, and then the Δψm was determined using a Mitocapture Apoptosis Detection kit (Biovision). In apoptotic cells, Mitocapture dye does not accumulate in mitochondria, rather, it remains as monomers in the cytoplasm and fluoresces green; in contrast in healthy cells, it accumulates in the mitochondria and fluoresces red. Tumor cell lines tend to undergo an increased rate of both growth and death compared with nontumor cells leading to some loss of Δψm. However, treatment with α-ESA led to a significant difference from controls (\( P < 0.001 \)) with 53% and 48% of the treated MDA-ERα7 and MDA-wt cells, respectively, having disruption of the mitochondrial membrane potential (Δψm; Fig. 3A). The addition of α-tocotrienol returned the Δψm to the level of the control cells. The loss of Δψm can precipitate translocation of AIF and endonuclease G (endoG) out of the mitochondria and into the nucleus resulting in apoptosis. To test for this, we treated cells with α-ESA for various time periods and then stained them for AIF and endoG. As shown in Fig. 3B (MDA-wt) and C (MDA-ERα7), the majority of both AIF and endoG are in the cytoplasm with a small amount in the nucleus before α-ESA treatment, consistent with where you would expect to find mitochondria before α-ESA treatment. However, as soon as 1 hour after the addition of α-ESA for the MDA-wt and after 4 hours for the MDA-ERα7 cells, the nuclei of the cells were brighter green than before α-ESA treatment, suggesting that both AIF and endoG translocated from the mitochondria to the nuclei after treatment with α-ESA. Integration of these results suggests that α-ESA is activating apoptosis in part via the intrinsic pathway.

**Lack of caspase involvement in α-ESA anticancer affects.**

To determine if the caspase cascade and PARP are required for α-ESA-initiated apoptosis, we performed proliferation assays using the broad spectrum caspase inhibitor BOC-D(OMe)-FMK. One-hour pretreatment of the cells at 37°C with 20 μmol/L BOC-D(OMe)-FMK did not alter the ability of α-ESA to inhibit proliferation of either the MDA-ERα7 or the MDA-wt cells (Fig. 4A), although treatment with α-tocotrienol blocked the anticancer effects of α-ESA as before (Fig. 2A). To further clarify if the caspase cascade was involved, we performed Western blot analysis for cleaved PARP that represents one of the steps at the bottom of the caspase cascade. Full-length PARP was readily observed but cleaved PARP was not detected after 0, 4, 8, 24, or 48 hours of incubation with α-ESA (Fig. 4B) for either the MDA-ERα7 or the MDA-wt cells. The amount of full-length PARP did not change when normalized to actin for the MDA-ERα7 cells, although the amount of full-length PARP did decline at the 48-hour time point in the MDA-wt cells. Taken together, these data indicate that α-ESA can block proliferation through a caspase-independent mechanism.
Discussion

We are the first to show direct inhibition of human breast cancer cell proliferation by α-ESA, a LC-PUFA that makes up ~60% of bitter melon seed oil. We found that α-ESA was able to inhibit proliferation as well as to induce apoptosis regardless of whether the cells were ER responsive or ER unresponsive (Fig. 1A). In addition, the concentration of α-ESA needed for inhibition was considerably lower than that of CLA. Previous studies found that bitter melon seed or fruit extracts were capable of anticancer activity in a rat colonic aberrant crypt foci model (18), a mouse skin carcinogenesis model (19), a DLD-1 (colorectal adenocarcinoma) mouse xenograft model (10), and a mouse mammary tumor model (6). Therefore, although a number of studies have suggested that various bitter melon components/extracts have anticancer activity, no prior work has evaluated the specific effects of α-ESA in relation to breast cancer.

We have investigated the mechanism of how pure α-ESA may inhibit tumorigenesis by means of a number of in vitro assessments. Our work has identified two potential parts of the mechanism. First, there seemed to be a direct effect on human breast cancer cells via lipid peroxidation. Lipid peroxidation has been implicated as a possible anticancer mechanism for LC-PUFAs. For example, it was shown that eicosapentaenoic acid (EPA), a LC-PUFA found in fish oil, inhibited DLD-1 human colon cancer xenograft growth through a lipid peroxidation mechanism (20). A separate study found that α-tocopherol blocked the ability of fish oil to suppress N-methyl-N-nitrosourea–induced mammary tumors in Sprague-Dawley rats (21). Additionally, female nude mice implanted with MDA-MB-231 human breast cancer cells, the parental cell line for our MDA-ERα7 cell line, exhibited decreased tumor growth when fed increasing amounts of fish oil compared with corn oil–fed controls (22). Interestingly, the addition of antioxidants to the diet decreased this protective effect of fish oil (22). Moreover, an in vitro study with MDA-MB-231 cells found that doxorubicin inhibition of cell proliferation was increased by treatment with another fish oil–associated LC-PUFA, docosahexaenoic acid and that the affect was abolished by α-tocopherol (23). Despite these studies, it has been shown that some antioxidants such as vitamin E and β carotene may be able to function as prooxidants under certain conditions (24, 25) and α-tocotrienol may therefore be oxidizing α-ESA. Thus, although these studies support our findings that α-ESA action may be dependent on an oxidation mechanism, it...
will require additional work before we can definitively say that lipid peroxidation plays an important role in the anticancer actions of LC-PUFA.

The idea that oxidative stress could lead to anticancer effects may be initially counterintuitive because it is well-documented that in certain model systems, antioxidants have tumor inhibitory effects. However, it has been shown that reactive oxygen and nitrogen species can have multiple roles in the cell, i.e., low levels allow normal protective signaling, intermediate levels lead to cellular damage and tumorigenesis, and high levels can result in an oxidative burst and cell death (for review, see ref. 26). It is possible that α-ESA inhibits breast cancer cell proliferation through a similar oxidation-dependent mechanism characteristic of an oxidative burst.

A second aspect of how α-ESA may inhibit breast cancer growth is through activation of AMPK. Work with antidiabetic drugs supports this potential mechanism of action. For example, a chemical dubbed “exercise in a pill” by the media, aminomimidazole carboxamide ribonucleotide (AICAR), activates AMPK and is being investigated as an antidiabetic drug. AICAR administration increased running endurance by 44% in normally sedentary mice (27). In addition, the percent of white adipose tissue relative to body weight was significantly decreased in AICAR-treated mice compared with untreated controls. As mentioned above, body fatness has been implicated in the risk of postmenopausal breast cancer, and as such, a reduction in white adipose tissue as seen with AICAR or other AMPK-activating mechanisms may result in inhibition of breast cancer. Metformin is a first line treatment for type 2 diabetes that has been implicated as a potential antineoplastic agent for breast cancer (28). Metformin also functions in part by activation of AMPK. Previous studies found that stimulation of AMPK by metformin resulted in a significant repression of cell proliferation in both ERα-negative MDA-MB-231 and ERα-positive MCF-7 and T47D breast cancer cells (29). In addition, the World Cancer Research Fund/American Institute for Cancer Research report found that exercise, such as what AICAR may simulate, was linked to a probable decrease in breast cancer risk (30). It is possible that AICAR and similar biologically active compounds could decrease breast cancer risk by simulating exercise. Here, we found that inhibition of AMPK partially blocked the effects of α-ESA (Fig. 6), suggesting that α-ESA may be functioning in part through a mechanism similar to AICAR and metformin.

The question of how much α-ESA would be required for in vivo anticancer actions is challenging to address because it has not yet been investigated in humans. However, 100 μmol/L EPA was capable of inhibiting proliferation of multiple cell lines including the MDA-MB-231, T-47D, MCF-7, KPL-1, and MKL-F (31, 32). In addition, when human subjects with a history of colorectal adenomas were given EPA at 2 grams per day for 3 months, levels of EPA increased in normal colonic mucosa, and this was associated with significantly reduced proliferation and increased mucosal apoptosis (33). It is likely that α-ESA will exert an even greater ability to inhibit breast cancer in vivo than EPA because the MDA-wt cells were inhibited 42% at 100 μmol/L concentrations with EPA (31), which is considerably less than the 97% inhibition we found with 80 μmol/L α-ESA (Fig. 1A). In addition, previous work with α-ESA has shown that a portion of the amount ingested does arrive at distant tumor sites (10). In vivo work with tung oil (70% α-ESA) in a DLD-1 xenograft model illustrated that 1% of dietary intake was enough to have significant effects on tumor growth (10). Work with the rats that were treated with azoxymethane to induce colonic aberrant crypt foci using bitter melon seed extract (~60% α-ESA) found that rats fed the extract had significantly fewer aberrant crypt foci compared with control rats at doses of 0.01%, 0.1%, and 1% of total caloric intake (18). Therefore, it should be possible to attain anti-breast cancer effects with α-ESA, although more studies are clearly needed.

In summary, many studies indicate that the type of dietary fat may be pivotal for inhibition of breast cancer. Here, we have characterized how α-ESA, a LC-PUFA, impacts breast cancer cell lines in vitro. This work should be useful first for defining preclinical studies and eventually in making dietary recommendations to women concerning their intake of α-ESA, which humans cannot synthesize de novo and as such must be obtained from dietary sources. Although bitter melon extract is available commercially, the specific actions of α-ESA on breast cancer have not been fully studied. The combination of known health benefits with an active market for supplements has led to many claims of health benefits for bitter melon extract but few scientifically proven actions. Our study has provided novel information concerning the use of α-ESA in cancer inhibition.

Disclosure of Potential Conflicts of Interest
